

Envy, Multi Envy, and Revenue Maximization

Amos Fiat and Amiram Wingarten

School of Computer Science, Tel Aviv University

Abstract. We study the envy free pricing problem faced by a seller who wishes to maximize revenue by setting prices for bundles of items. Consistent with standard usage [9] [10], we define an allocation/pricing to be *envy free* if no agent wishes to replace her allocation (and pricing) with those of another agent.

If there is an unlimited supply of items and agents are single minded then we show that finding the revenue maximizing envy free allocation/pricing can be solved in polynomial time by reducing it to an instance of weighted independent set on a perfect graph.

We also consider a generalization of envy freeness. We define an allocation/pricing as *multi envy free* if no agent wishes to replace her allocation with the union of the allocations of some set of other agents and her price with the sum of their prices. We show that even though such allocation/pricing can be approximated by $O(\log m + \log n)$ factor [3], it is *coNP*-hard to decide if a given allocation/pricing is multi envy free. We also show that revenue maximization multi envy free allocation/pricing is *APX* hard.

An interesting restricted version of the subset pricing problem is when all items are intervals of a line segment and all requests are a contiguous set of items along the line. The motivation here is that one can think of the agents as drivers on a highway when each product is highway segment (or guests in a hotel — items are translated to dates). In this setting, determining if a given allocation/pricing is multi envy free is polynomial time. If the highway has bounded capacities then a revenue maximizing envy free allocation/pricing can be computed in polynomial time and we also give an FPTAS for the revenue maximizing multi envy free allocation/pricing.

1 Introduction

We consider the combinatorial auction setting where there are several different items for sale, not all items are identical, and agents have valuations for subsets of items. We allow the seller to have identical copies of an item. We distinguish between the case of limited supply (e.g., physical goods) and that of unlimited supply (e.g., digital goods). Agents have known valuations for subsets of items. We assume free disposal, i.e., the valuation of a superset is $\geq$ the valuation of a subset. Let S be a set of items, agent i has valuation $v_i(S)$ for set S . The valuation functions, v_i ,

are public knowledge. Ergo, we are not concerned with issues of truthfulness or incentive compatible bidding. Our concern here is to maximize revenue in an envy free manner.

Our goal is to determine prices for sets of items while (approximately) maximizing revenue. The output of the mechanism is a payment function p that assigns prices to sets of items and an allocation a . Although there are exponentially many such sets, we will only consider payments functions that have a concise representation. For a set of items S let $p(S)$ be the payment required for set S . Let a_i be the set assigned to agent i .

In general, every agent i has valuation function v_i defined over every subset of items.

Given a payment function p , and a set of valuation functions v_i , let $z_i = \max_S (v_i(S) - p(S))$, and let $\mathcal{S}_i$ to be a collection of sets such that $S \in \mathcal{S}_i$ if and only if $v_i(S) - p(S) = z_i$.

We now distinguish between two notions of envy freeness.

Definition 1 *We say that (a, p) are envy free if*

- *If $z_i > 0$ then $a_i \in \mathcal{S}_i$.*
- *If $z_i = 0$ then either $a_i \in \mathcal{S}_i$ or $a_i = \emptyset$.*
- *If $z_i < 0$ then $a_i = \emptyset$.*

Definition 2 *If $a_i = \emptyset$ then we say that agent i loses, otherwise we say that agent i wins.*

Definition 3 *A pricing p is monotone if for each subset S and for each collection of subsets C such that $S \subseteq \bigcup_{T \in C} T$ the following inequality holds: $p(S) \leq \sum_{T \in C} p(T)$.*

Definition 4 *An allocation/pricing (a, p) is multi envy free if it is envy free and its pricing is monotone.*

Clearly, multi envy-freeness is a more demanding requirement than envy-freeness, so any allocation/pricing that is multi envy-free is also envy-free. In item pricing, a price is set for every item, identical copies of an item are priced the same, and the price of a set is the sum of the individual item prices. In subset pricing one may assign a sets of items prices that cannot be consistently expressed as a sum of the item prices comprising the set. E.g., discounts for volume would not generally be consistent with item pricing.

In the unlimited supply setting, item pricing is always multi envy-free (and hence also envy-free). With a limited supply of items, achieving

item-pricing [multi] envy-freeness is not automatic. Circumstances may arise where some agent has a valuation less than the price of some set of items she is interested in, but there is insufficient supply of these items. An envy-free solution must avoid such scenarios. Even so, for limited or unlimited supply, item pricing is envy-free if and only if item pricing is multi envy-free (this follows from the monotonicity of the item pricing).

For subset pricing, it does not necessarily follow that every allocation/pricing that is envy-free is also multi envy-free.

Although the definitions above are valid in general, we are interested in single minded bidders, and more specifically in a special case of single minded bidders called the highway problem ([13,2]) where items are ordered and agents bid for consecutive interval of items.

2 Our Results

Table 1 gives gaps in revenue between the item pricing (where envy freeness and multi envy freeness are equivalent), multi envy freeness, and envy freeness. These gaps are for single minded bidders, and the gaps between item pricing and multi envy free subset pricing are in the context of the highway problem. In all cases (single minded bidders or not)

$$\begin{aligned} \text{Revenue}([\text{Multi}] \text{ EF item pricing}) &\leq \text{Revenue}(\text{Multi EF subset pricing}) \\ &\leq \text{Revenue}(\text{EF subset pricing}) \\ &\leq \text{Social Welfare}. \end{aligned}$$

Clearly, if a lower bound holds for unlimited supply it clearly also holds for (big enough) limited supply.

All of our lower bound constructions are for single minded bidders, for single minded bidders with unlimited supply the bounds are almost tight as

$$(\text{Social welfare})/(\text{Envy-free item pricing}) \leq H_m + H_n.$$

This follows directly from [13], see below.

For limited supply, lower bound # 1 shows for some inputs the revenue of [Multi] Envy-free item pricing can be significantly smaller (by a factor $\leq H_n/n$ or $\leq H_m/m$) than the revenue of Multi envy-free subset pricing. This gap is smaller for unlimited supply, lower bound # 3 shows that for unlimited supply it is possible to achieve a ratio of $1/H_n$ or $1/\log \log m$ between the revenue of [Multi] Envy-free item pricing and that of Multi

	Lower Bound	[Multi] Envy-free item pricing	Multi envy-free subset pricing	Envy-free subset pricing	Type of Instance
Limited	#1	H_n H_m	n m		Highway
Unlimited	#2		1 1	H_n H_m	Single Minded
Unlimited	#3	1 1	H_n $\log \log m$		Highway

Table 1. Revenue gaps for single minded bidders (n - # items, m - # agents).

envy free subset pricing. Both lower bounds # 1 and # 3 are for the highway problem.

Lower bound # 2 in Table 1 shows a gap in revenue ($1/H_n$ or $1/H_m$) between Multi envy-free subset pricing and Envy-free subset pricing. This bound is for single minded bidders, but not for the highway problem.

We further give several hardness results and several positive algorithmic results:

1. For unlimited supply, and single minded bidders, we show that finding the envy free allocation/pricing that maximizes revenue is polynomial time.
2. We show that the decision problem of whether an allocation/pricing is multi envy free is *coNP*-hard.
3. We also show that finding an allocation/pricing that is multi envy free and maximizes the revenue is *APX*-hard.
4. For the the highway problem, we show a that if all capacities are $O(1)$ then the (exact) revenue maximizing *envy free* allocation/pricing can be computed in polynomial time. *I.e.*, the problem is fixed parameter tractable with respect to the capacity.
5. Again, for the highway problem with $O(1)$ capacities, we give a FPTAS for revenue maximization under the more difficult Multi envy-free requirements.

3 Related Work

Much of the work on envy free revenue maximization is on item pricing rather than on subset pricing. Guruswami et al. [13] give an $O(\log m + \log n)$ -approximation for the general single minded problem, where n is the number of items and m is the number of agents. This result was extended by Balcan et al. [3] to an $O(\log m + \log n)$ -approximation for

arbitrary valuations and unlimited supply using single fixed pricing which is basically pricing all bundles with the same price. Demaine et al. [8] show that the general item pricing problem with unlimited availability of items is hard to approximate within a (semi-)logarithmic factor.

The general combinatorial auction setting allows agents to request any arbitrary set of items. Even for unlimited supply, the problem of maximizing the revenue is hard to approximate within a (semi-)logarithmic factor [8] (and shown to be APX hard for a restricted case called the “graph vertex problem” where agents are interested in sets of one or two items only [13]).

If every agent has an associated set of items such that the agent values any nonempty subset equally, [13] present a $O(\log n)$ approximation algorithm. Briest and Krysta [5] show that the revenue maximization problem is inapproximable within $O(\log^\epsilon m)$ for some $\epsilon > 0$. This indicates that we can not expect to do better in the more general setting where valuations are for bundles and agents are not single minded.

For the limited supply general problem it is easy to show that it is NP-hard to approximate it within m or $n^{1/2}$ as noted by Cheung and Swamy in [7] (Grigoriev et al. [11] show that it is NP-complete to approximate the maximum profit within a factor $m^{1-\epsilon}$, for any $\epsilon > 0$ even when the underlying graph is a grid). [7] gives an $O(\sqrt{n} \log u_{max})$ approximation for envy free profit maximization problem (where $u_{max} = \max$ item supply).

The Highway Problem

For the unlimited supply the problem is NP-hard (Briest and Kriesta [4]). Also the problem is given $O(\log n)$ -approximation by [2]. When the length of each interval is bounded by a constant or the valuation of each agent is bounded by a constant, Guruswami et al. [13] give a fully polynomial time approximation scheme (FPTAS). If the intervals requested by different agents have a nested structure then an FPTAS is possible [2,4].

For limited supply when the number of available copies per item is bounded by C , Grigoriev et al. [11] propose a dynamic programming algorithm that computes the optimal solution in time $O(n^{2C} B^{2C} m)$, where n is the number of agents, m the number of items, and B an upper bound on the valuations. For C constant, and by appropriately discretizing B , this algorithm can be used to derive an FPTAS for this version of the highway problem. However, the solution produced by this algorithm need not be envy-free. For the highway problem with uniform capacities, [7] gives an $O(\log u_{max})$ approximation algorithm where all capacities are equal, this algorithm does produce an envy-free allocation/pricing.

4 Notation and Definitions

In our setting we have m agents and n items.

The capacity of an item is the number of (identical) copies of the item available for sale. The supply can be *unlimited supply* or *limited supply*. In a *limited supply* seller is allowed to sell up to some fixed amount of copies of each item. In the *unlimited supply* setting, there is no limit as to how many units of an item can be sold.

We consider *single-minded* bidders, where each agent has a valuation for a bundle of items, S_i , and has valuation 0 for all sets S that are not supersets of S_i . The valuation function for i , v_i , has a succinct representation as (S_i, v_i) where $v_i = v_i(S_i)$. For every S such that $S_i \subseteq S$, $v_i(S) = v_i(S_i) = v_i$, for all other sets S' , $v_i(S') = 0$.

If $a_i = S$ and $S_i \subset S$, we can change the allocation to be $a_i = S_i$ and keep the same price. The original allocation/pricing is envy free if and only if the modified allocation is also envy free. Therefore, we can say without loss of generality, that an allocation/pricing must either have $a_i = \emptyset$ and $p_i(a_i) = 0$ or $a_i = S_i$ and $p_i(a_i) \leq v_i(S_i)$.

We denote the set of agents i allocated S_i (the winning agents) $W = \{i : a_i \neq \emptyset\}$ to be the set of agents for which $a_i = S_i$. Our goal is to find an allocation/pricing that maximizes

$$\sum_{i \in W} p(S_i).$$

For single minded bidders, we say that agent i wins if $i \in W$. Otherwise, we say that i loses.

Fix the price function p . For unlimited supply, it is easy to see that the revenue maximizing winner set $W = \{i : p(S_i) \leq v(S_i)\}$. For limited supply, it must be that

$$\{i : p(S_i) < v(S_i)\} \subseteq W \subseteq \{i : p(S_i) \leq v(S_i)\}.$$

4.1 Envy and Multi Envy for Single minded bidders

For single minded bidders, the definitions of envy free and multi envy free can be simplified as follows:

Observation 5 *For single minded bidders an allocation/pricing is envy free if and only if*

1. *For any two winning agents i and j , if $S_i \subseteq S_j$, it holds that $p(S_i) \leq p(S_j)$*

2. For each losing agent i and winning agent j such that $S_i \subseteq S_j$ it holds that $v(S_i) \leq p(S_j)$

Observation 6 *For single minded bidders an allocation/pricing is multi envy free if and only if*

1. For any winning agent i and any collection of winning agents C such that $S_i \subseteq \bigcup_{j \in C} S_j$ the following must hold: $p(S_i) \leq \sum_{j \in C} p(S_j)$
2. For any losing agent i and any collection of winning agents C such that $S_i \subseteq \bigcup_{j \in C} S_j$ the following must hold: $v(S_i) \leq \sum_{j \in C} p(S_j)$.

5 Revenue Gaps Between Models

In this section we show the gaps between the optimal solutions of the different models. It is clear that item pricing envy free setting is less profitable than the subset pricing multi envy free setting since any item pricing solution is also multi envy free solution. We give two theorems that show the gaps between the two models when items are given in limited supply and when items are given in unlimited supply.

The following theorem corresponds to line #1 in Table 1.

Theorem 7 *The maximal revenue in an envy-free item pricing for the limited supply highway setting may be as low as $\frac{H_k}{k}$ times the maximal revenue achievable by a subset pricing that is multi envy free (where H_k is the k 'th Harmonic number, and k is the maximal capacity of an item).*

Proof. Consider a path of k segments where segment 1 has capacity of k and for $i > 1$, segment i has capacity $n - i + 1$. There are two groups of agents in the setting:

- k agents: $\{ \text{request } [1, i] \text{ with valuation of } 1 \mid 1 \leq i \leq k \}$
- $k - 1$ agents: $\{ \text{request } [i, i] \text{ with valuation of } \frac{1}{i} \mid 1 \leq i \leq k \}$

See Figure 1 for illustration.

Clearly the best an item pricing envy-free solution can achieve is H_k by assigning price of $\frac{1}{i}$ to segment i . A subset pricing multi envy free solution can price all intervals on the path at 1 and get a revenue of k .

The number of requests is $O(k)$, therefore the gap is $O(m/H_m)$.

We now deal with the gaps between item pricing setting, multi envy free setting and envy free setting when items are given in unlimited supply. It is clear that any item pricing solution is also multi envy free

Fig. 1. The most profitable agents are the one with valuation 1, however allocating them with their bundles makes the others envy

solution and that any multi envy free solution is also an envy free solution. The question is how big can the gap be, how more can a seller profit by choosing another concept of envy? Guruswami et al. [13] give an $O(\log m + \log n)$ -approximation for the general item pricing problem. The upper bound used is the sum of all valuations. Since any item pricing solution is also multi envy free and since the sum of all valuations can be used as an upper bound on multi envy free and envy free solutions, we conclude that the gap between any pair of these problems is upper bounded by $O(\log m + \log n)$. We show lower bounds on the gaps. The following theorem corresponds to line #3 in Table 1.

Theorem 8 *Multi envy free subset pricing setting for the unlimited supply problem (even for a highway) can improve the optimal item pricing solution by a factor of $O(\log \log m)$ where m is the number of requests.*

Proof. We construct the following agent requests along a path. We assume for simplicity that n , the number of items, is a power of 2, so $n = 2^k$. We have $k + 1$ layers of requests, starting from layer 0 up to layer k . In layer i there are 2^i equal sized requests, each for 2^{k-i} items, of valuation $\frac{1}{2^i(k-i)}$. See Figure 2. The multi envy-free pricing can accept all requests and achieve revenue $O(H_k)$ while item pricing can produce at most $O(1)$ revenue. Since $k = O(\log m)$ this shows that the ratio between [multi]

envy-free item pricing revenue and multi envy free subset pricing revenue can be as low as $O(1/\log \log m)$.

Fig. 2.

The following theorem corresponds to line #2 in Table 1.

Theorem 9 *Envy free subset pricing setting for the unlimited supply problem can improve on the optimal multi envy free allocation/pricing solution by a factor of $O(\log m)$ where m is the number of requests.*

Proof. We construct an instance with m agents and m items. The set of all items is denoted $V = \{1, \dots, m\}$. For agent i we have $S_i = V \setminus \{i\}$ with valuation $v_i = \frac{1}{i}$. Since every request is a subset of the union of any two other requests, the minimal $v_i + v_j$ where v_i and v_j both, is an upper bound on the revenue that can be achieved from any allocated request in the multi envy free setting. Let the two lowest winning valuations be i_α and i_β . All requests with lower valuations are not allocated. All requests with valuation higher than i_α and i_β can have price that is at most $\frac{1}{i_\alpha} + \frac{1}{i_\beta}$. Therefore no multi envy free allocation/pricing can achieve more than revenue 2.

On the other hand, in the envy free setting, an allocation of each request at price $p_i = v_i$ is valid and achieves revenue of H_m . Therefore, the ratio between maximal revenue achieved in the multi envy free setting vs. the maximal revenue achieved in the envy free setting can be as low as $O(1/\log m)$.

6 Polynomial time envy-free revenue maximization (unlimited supply, single minded bidders)

We discuss in this section the classical envy free approach where each agent may envy only one other agent (not a group of other agents). Therefore we seek an allocation/pricing such that Observation 4.1 is valid.

With limited supply of items, a reduction from independent set can be used to show that the problem of maximizing revenue is hard to approximate within $m^{1-\epsilon}$. Grigoriev et al. [11] show that it is NP-complete to approximate the maximum profit limited supply item pricing solution to within a factor $m^{1-\epsilon}$, for any $\epsilon > 0$ even when the underlying graph is a grid. The same construction can be used here.

For the unlimited supply setting we show that:

Theorem 10 *For single minded bidders the revenue maximizing envy free allocation/pricing with unlimited supply can be computed in polynomial time.*

Our idea is to make use of the fact that allocating a certain request at price p means that any request that is a superset and has valuation $< p$ must not be allocated. We transform all requests into a directed acyclic perfect graph H and then compute the revenue maximizing allocation/pricing by computing a maximal independent set on H (which can be done in polynomial time for perfect graph). A similar construction using the hierarchical nature of a pricing was done by Chen et al. [6] for envy free pricing of products over a graph with metric substitutability.

As before, agent i seeks bundle S_i and has valuation v_i .

6.1 Construction of Graph H

For each $i \in \{1, \dots, m\}$, define

$$A(i) = \{1 \leq j \leq m \mid S_i \subseteq S_j \text{ and } v_j < v_i\}.$$

The reason we consider only requests with lower valuations is that when picking i 's price only these allocations are at risk. Given price p for agent i , all requests in $A(i)$ with valuation $< p$ cannot be allocated at any price.

For each agent i , define an ordering π_i on $A(i)$ in non-decreasing order of valuation. I.e., for each pair j, k such that $1 \leq j \leq k \leq n_i$, where $n_i = |A(i)|$, the valuations must be ordered, $v_{\pi_i(j)} \leq v_{\pi_i(k)}$ (ties are broken arbitrarily).

We construct an undirected vertex-weighted graph H as follows. For each $i \in V$ we associate $n_i + 1$ weighted vertices in H . These vertices constitute the $T(i)$ component, the vertices of which are $\{i_1, i_2, \dots, i_{n_i+1}\}$. The set of all H vertices is defined as $\bigcup_{i \in V} T_i$. The weight of each vertex in $T(i)$ is:

$$\begin{aligned} w(i_1) &= v_{\pi_i(1)} \\ w(i_2) &= v_{\pi_i(2)} - v_{\pi_i(1)} \\ &\vdots \\ w(i_n) &= v_{\pi_i(n_i)} - v_{\pi_i(n_i-1)} \\ w(i_{n_i+1}) &= v_i - v_{\pi_i(n_i)} \end{aligned}$$

By definition of $A(i)$ and π_i , all weights are non-negative and

$$\sum_{j \in T(i)} w(j) = v_i.$$

For each $T(i)$ component we connect the various vertices of $T(i)$ to components $T(j)$ such that $j \in A(i)$ (connecting a vertex $i_k \in T(i)$ to a component $T(j)$ means connecting i_k to all vertices of $T(j)$ by edges) as follows. Vertex i_{n_i+1} is connected to all components $T(j)$ for $j \in A(i)$. Vertex i_k is connected to all components $T(\pi_i(j))$ for each j such that $1 \leq j < k$. For instance, vertex i_2 is connected to component $T(\pi_i(1))$, vertex i_3 is connected to components $T(\pi_i(1))$ and $T(\pi_i(2))$, and so on. As i is not contained in $A(i)$ there can't be self edges. It is easy to see that for any $a < b$, i_b is connected to each component that i_a is connected to (and maybe to some additional components).

See Figure 3 for the exact construction of edges from a component $t(i)$. Figure 4 shows an example of transforming a pricing problem into the graph H .

Lemma 11 *The value of the maximum weighted independent set on H is equal to the revenue obtained from the optimal envy free pricing of the original problem.*

Proof. When picking vertices for the maximal independent set instance, in every component $T(i)$ one must choose vertices whose sum equals the valuation of agent j , where $j \in A(i)$ or $j = i$. A component that none of its vertices were picked means that agent i was not allocated her set. The construction of H ensures that the pricing is envy-free. We prove that

a maximal revenue envy-free allocation/pricing can be translated into an independent set in H and that a maximal independent set in H can be translated into a revenue maximizing envy free allocation/pricing.

(*envyfree* $\Rightarrow$ *IS*) We show how to construct an independent set solution in H from the optimal allocation/pricing of the original pricing instance. It is easy to see that the price p_i is equal to one of the valuations v_j for j such that $j \in A(i)$ or $j = i$ (otherwise the prices can be increased). We will pick vertices in $T(i)$ to achieve price of p_i . Let us assume that $p_i = v_j$ for some j such that $j \in A(i) \cup \{i\}$. We will pick all vertices of $i_k \in T(i)$ such that $k \leq \pi(j)$. By construction of $T(i)$ our pick gives an accumulated value of $v_j = p_i$. As we have a valid pricing we can assume that $\forall i, j : S_i \subset S_j \Rightarrow p_i \leq p_j$. Let us assume by contradiction that our pick is not a valid independent set. It follows that there are two vertices i_k and j_m such that $j \in A(i)$ and there is an edge between them. Since edges are drawn from i_k to all components that represent requests that have lower valuation than $\sum_{1 \leq t < k} w(i_t)$ we get that p_j must be less than p_i ($p_i \geq \sum_{1 \leq t < k} w(i_t)$). This contradicts our assumption.

(*IS* $\Rightarrow$ *envyfree*) Assuming we have an optimal independent set solution in H . By H construction, in each component $T(i)$ any node i_k is connected to all neighbors of i_m for $m < k$. Therefore the vertices set that are picked as part of the independent set in each component $T(i)$ is of the form $\{i_k | k \leq i^{max}\}$. We transform the independent set solution into a pricing as follows:

- Agent i such that none of $T(i)$'s vertices were picked receives nothing.
- Agent i such that the vertices $\{i_k | k \leq i^{max}\}$ were picked in $T(i)$ receives S_i at price $\sum_{k \leq i^{max}} w(i_k)$

Fig. 3. Construction of H

Assume that the pricing is not envy-free and we have requests i, j such that $S_i \subset S_j$ and $p_i > p_j$. By the construction of H we can assume that p_i and p_j are equal to $v_{i'}$ and $v_{j'}$ such that $i' \in A(i)$ and $j' \in A(j)$. We picked from $T(i)$ vertices $\{i_k : 1 \leq k \leq i^{max}\}$ such that $\sum_{1 \leq k \leq i^{max}} w(i_k) = v_{i'}$. The same goes for $T(j)$.

Let's inspect the vertices in $T(j)$ that should have been picked in order to make $p_j \geq p_i$.

Define $\mathcal{J}$ as the minimal set of vertices in $T(j)$ of the form $\{j_k | j^{max} < k \leq t\}$ such that $\sum_{1 \leq k \leq t} w(j_k) \geq p_i$. The vertices of $\mathcal{J}$ has outgoing edges (from i to $A(i)$) into components $T(k)$ such that $k \in A(i)$ (requests that are superset of j and i and have lower valuation than i).

The vertices reachable from $\mathcal{J}$ by the outgoing edges are reachable also by $i_{i^{max}}$. Hence we are guaranteed that they are not picked. Also we know that all vertices that have edges into $\mathcal{J}$ were not picked as picking one of them would have prevented picking any of $T(j)$'s vertices.

Therefore there is no reason for the independent set not to pick also the vertices of $\mathcal{J}$ and increase the independent set value. This contradicts the maximality of the independent set solution.

Lemma 12 *H is a comparability graph*

Proof. Let us direct the edges of H . In case of edge from node of $T(i)$ to node of $T(j)$ the direction will be from i to j if $j \in A(i)$.

This orientation assignment results a directed graph with transitivity: if we have directed edge from i_α to j_β and from j_β to k_γ , we show that there must be directed edge from i_α to k_γ .

Note that since $k \in A(j)$ and $j \in A(i)$ then $k \in A(i)$ as $A(j) \subset A(i)$. The fact that there is directed edge from j_β to $T(k)$ means that $v_j > v_k$, therefore in π_i order it will also be higher (And to the right in Figure 3).

Since i_α is connected to all components $T(\pi_i(l))$ such that $1 \leq l < \alpha$ and i_α is also connected to $T(j)$, i_α must be connected to $T(k)$ as well (as $\pi_i^{-1}(k) < \pi_i^{-1}(j)$). Clearly i_α is connected to each node of $T(k)$ including k_γ .

We've shown that the edges of the graph can be oriented so that the transitivity property is maintained. Therefore the graph is a comparability graph.

A graph is said to be perfect if the chromatic number (the least number of colors needed to color the graph) of every induced subgraph equals the clique number of that subgraph. Showing that H is a comparability graph implies the following corollary:

Corollary 13 *H is a perfect graph.*

We know that the maximal weighted independent set can be solved in polynomial time on perfect graphs [12]. By Lemma 11 and Lemma 12 we conclude that finding the optimal envy free allocation/pricing in the most general single minded setting can be done in polynomial time. This completes the proof of Theorem 10.

7 Hardness of multi envy-free allocation/pricing

In this section we show the following hardness results:

- The problem of deciding whether a certain pricing assignment is multi envy free is *coNP*-hard.
- Maximizing revenue from single minded agents subject to multi envy free pricing is *APX*-hard.

Theorem 14 *The problem of deciding whether a certain pricing assignment is multi envy free is coNP-hard.*

Proof. We show a polynomial reduction from *VERTEX-COVER*(k) to our decision problem. Assume that there is an algorithm $\mathcal{A}$ that confirm the envy-freeness of a given subset pricing. The NP-hard problem of *VERTEX-COVER*(k) can be reduced to this problem. The building of subset pricing from *VERTEX-COVER*(k) instance is as follows:

- Each edge turns into an item.
- Each vertex turns into a set with price 1.
- Give the price $k - 1$ to the set of all items.

(Note that this is a limited supply setting where each item is chosen by 3 subsets at most.)

Clearly $\mathcal{A}$ confirms that this instance is not legal if and only if there is a vertex cover to the *VERTEX-COVER* instance of size k .

Since *VERTEX-COVER* is *NP-hard* this imply that The problem of deciding weather a certain pricing is envy-free is *coNP-hard*.

Note that even though deciding whether a pricing is multi envy free is hard, finding such a pricing can be approximated. Balcan et al. [3] showed $O(\log m + \log n)$ -approximation for arbitrary bundle valuations and unlimited supply using single fixed pricing which is basically pricing all bundles at the same price. Such a pricing is multi envy free pricing as well.

Theorem 15 *Maximizing revenue from single minded agents subject to multi envy free pricing is APX-hard, even when all agents are interested in at most two items.*

Proof. We show that finding the optimal multi envy free pricing is APX-hard by a reduction from MAX-2SAT. Given a MAX-2SAT instance we build multi envy free allocation instance as follows.

Let's denote C as the number of clauses in the SAT and $C^{(v)}$ the number of clauses containing variable v .

Items in the allocation problems are:

- For each literal we have an item to sell. Thus for each variable there are two items, one for the variable and one for its negation.

Agents in the allocation are:

- For each literal of variable v we have two sets of $10C^{(v)}$ agents each. For one set all valuations are 3 and for the other all valuations are 2.
- For each variable v we have set of $15C^{(v)}$ agents that wish to buy the variable's item and its negation's with valuation 5.
- For each disjunction clause there is a single agent that wishes to buy both literals of the clause with valuation 5.

We show that there is a pricing with revenue at least $314C + k$ if and only if there is a solution to the 2SAT instance that satisfies at least k clauses.

Let us prove the easy direction. Assume that there is a solution to the MAX-2SAT problem that satisfy at least k clauses. Assign a price of 3 to each request for a literal that is set to true in the solution. Assign a price of 2 to each request for literals that are set to false in the solution. Assign a price of 5 for each clause request. Each variable request is priced at 5. This gives a valid multi envy free pricing and we can verify that the revenue of it is $314C + k$.

For the other direction, let p be a pricing with maximum revenue, and assume the the revenue is at least $314C + k$. The optimal way to price variable and literal agents for variable v is be pricing one literal at 2 and the other at 3, in that way the variable requests for both literals is priced at 5 and the revenue from the variable and literals agents is $155C^{(v)}$. By the optimality of p , since variable and literals agents are always more profitable than the clause agents, all variables must be priced in this manner. Each clause can be priced at 4 if both its literals are priced at 2, or by 5 if one (at least) of its literals is priced at 3. In total this means that

from pricing allocation of revenue $314C + k$ defines a natural assignment to the MAX-2SAT problem by making literals priced at 3 to be true.

Because the maximum 2-SAT solution satisfy at least $\frac{1}{4}$ of the clauses, we are seek for a case where $k \geq \frac{c}{4}$. Some straightforward calculations shows that a $\frac{1256+\eta}{1257}$ approximation of the multi envy free pricing/allocation problem would yield an η -approximation to the MAX-2-SAT. This proves that multi envy free pricing/allocation problem is NP-hard to approximate to within $\frac{1256+\eta}{1257}$, where $\eta = .943$ is the approximation hardness constant for MAX-2SAT problem shown in [14].

8 The Highway Problem

The highway problem is the vertex problem pricing in the special case where the vertices are numbered $1, \dots, n$ and each agent is interested in an interval $[i, j]$.

8.1 Multi Envy Free Hardness Results

Theorem 16 *Multi envy free allocation/pricing for the highway problem is in NP.*

Proof. We give a polynomial time algorithm that verifies that a given pricing and allocation is envy free. The algorithm builds a directed graph over the same nodes of the highway, where for each segment $\mathcal{I}$ there is an edge for any allocated request i that contains $\mathcal{I}$, with weight v_i . Then the algorithm computes the shortest path for any allocated request's segment in order to find irregularities. See Algorithm 1.

Algorithm 1 Verifying a given allocation/pricing on the highway to be multi envy free

1. Create directed graph G where for each allocated bundle of price p there are directed edges between the first node and all other nodes in the bundle with weight p (see Figure 5)
 2. For each allocated bundle of price q and for each unallocated bundle with valuation q do:
 - Compute the shortest path in G between the first and last nodes of the bundle
 - If q is higher than the shortest path, return false (the allocation/pricing is not multi envy free)
 3. return true
-

Every path of weight w can be translated into a set of allocated bundles of total price w and vice versa. Therefore if there is no path shorter than q there is no set of requests that has total total price lower than q and the agent is not envious. In the other direction it is easy to see that if the algorithm finds a path which is shorter than q then this path can be translated into a set of agents that get the bundle at a lower price than q .

Theorem 17 *The problem of finding the revenue maximizing multi envy free solution for the highway problem is NP-hard.*

Proof. We show a polynomial time reduction from *PARTITION*, similar to the reduction of item pricing highway problem shown in [4]. The input to the partition instance is a multiset of weights $I = \{w_i\}$. For weight w_i we construct a weight component on the highway $\mathcal{W}_i$ which consist of three agents interested in item i :

- Request at price w_i
- Another request at price w_i
- Request at price $2w_i$

In addition another two agents are interested in purchasing all the items. Both of them with valuation $\frac{3}{2} \sum w_i$. See Figure 6.

The weight obtained from component $\mathcal{W}_i$ can be $2w_i$, or $3w_i$. $3w_i$ is achieved by pricing the item at w_i and accepting all agents with price w_i each. $2w_i$ is achieved by pricing the item at $2w_i$ and accepting only the third agent. In order to profit from the full valuations of the two agents interested in all items we need that the total price of all items be no more than $\frac{3}{2} \sum w_i$.

It can be argued that the maximum revenue is earned when there is a partition between components, when some of them earn $3w_i$ and some $2w_i$ and the two agents interested in all items pay their full valuations. There is a pricing that reach revenue of $\frac{9}{2}$ if and only if there is a partition of I into S and $I \setminus S$ such that the sum of weights in both is equal.

8.2 $O(1)$ Edge Capacities, Multi Envy Free Highway Allocation/Pricing

In the problem on a path with limited edge capacities, each edge $e \in E$ can accommodate no more than c_e allocated requests. Let $C = \max c_e$. Somewhat inspired by what's done in [11] we show that we can solve this

problem in time $O(m^{2C} B^{2C^2} n)$ by finding a longest path in an acyclic digraph.

Here is a useful definition of winner multi envy free allocation/pricing and a lemma that shows how to transform winner multi envy free allocation/pricing to multi envy free allocation/pricing.

Definition 18 *An allocation/pricing is winner multi envy free if for any winning agent i , its set S_i is not a subset of a union of other sets (of winning agents) for which the sum of the prices is strictly less than the price of the set S_i .*

Lemma 19 *Assume we have a winner multi envy free allocation/pricing for a subset pricing instance over a highway with revenue R . A multi envy free allocation/pricing can be computed in time $O(m^2)$ with revenue $\geq R$.*

Proof. Given an allocation/pricing that is winner multi envy free, one can convert it into an allocation/pricing that achieves at least the same revenue and is multi envy free.

For each agent i such that $a_i = \emptyset$ compute the cheapest (by pricing) collection B of winning agents such that $S_i \subset \cup_{j \in B} a_j$. This can be done by using shortest path algorithm on winning agents prices in the same way as Algorithm 1. If $v_i(S_i) \geq \sum_{j \in B} p(a_j)$ then agent i obeys the condition required for unallocated agents in multi envy free allocations.

If $v_i(S_i) < \sum_{j \in B} p(a_j)$, then we perform the following steps:

- Compute the cheapest (by valuation) collection C of winning agents such that $S_i \subset \cup_{j \in C} a_j$ (this can be done by the same way as before).
- For each agent j in C , if $p(j) < v_j$, set $p(j) = v_j$ and change the prices of any allocated agent k such that $S_j \cap S_k \neq \emptyset$ from $p(a_k)$ to the accumulated payment amount of the minimal weight (by payment) collection of agents that is superset of S_k . C contains the agents that are part of the cheapest set of agents among their path, therefore none of the agent prices can exceed their valuation.
- If $v_i(S_i) < \sum_{j \in C} p(a_j)$ then we assign agent i the set S_i , set $p_i(S_i) = \sum_{j \in C} p(a_j)$, and set $a_j = \emptyset$ for $j \in C$. Since each agent j in C was allocated with $p(a_j) = v_j$, making $a_j = \emptyset$ does not make j envious.

By doing each replacement we clearly still have a winner multi envy free solution. In addition, for each $j \in C$ there is no cheaper set of agents for S_j (otherwise these agents would have composed C instead of j), Therefore none of the agents in C is envious after the switch.

After m iterations the solution is multi envy free.

Theorem 20 *For a highway with n elements and m agents with maximal valuation B where the capacities of the edges are $\leq C$, there is a $O(m^{2C} B^{2C^2} n)$ time algorithm for the profit maximization multi envy free problem on a path.*

Proof. We create an n -layered digraph D with an additional source s and sink t , layers 0 and $n + 1$, respectively. There are arcs only between layers that represents neighboring items on the highway. Hence, in any $s \rightarrow t$ path, there are exactly $n + 2$ nodes.

In each node in layer e , corresponding to item e , we store all winning agents j that are accommodated by edge e . We store the total amounts all these agents spend on all items (network links) in their path. Moreover, we store for each pair $\langle i, j \rangle$ the value of the shortest possible path between first edge of i to current edge that accommodates j . Basically these values can be thought of as matrix $(A)_{i,j}$ of size $\leq C^2$ that holds in each cell the shortest paths between first edge of i to current edge that accommodates j , then the diagonal (i, i) represents the amount spent by i itself.

Any node x (more precisely, the path $s \rightarrow x$) in the digraph represents a feasible partial solution. Arcs from node x of layer e to node y of layer $e + 1$ are only introduced if the path $s \rightarrow y$ represents a feasible extension of the partial solution represented by the path $s \rightarrow x$. The weight on an arc that connects a node of layer e to a node of layer $e + 1$ is equal to the profit earned on edge $e + 1$, that is, the total amount that the new introduced allocated agents of edge $e + 1$ pay.

Therefore, the weight of the longest $s \rightarrow t$ path in digraph D is equal to the maximum total profit. Moreover, the set of winning agents can be reconstructed from the longest $s \rightarrow t$ path. Algorithm 2 shows a more formal description. The allocated agents in this allocation do not envy each other, however they can be envied by the losers (the allocation/pricing is *winner multi envy free*). Lemma 19 shows how to overcome this issue and produce *multi envy free* allocation/pricing.

Lemma 21 *There is a $O(m^{2C} B^{2C^2} n)$ time algorithm that produces optimal winner multi envy free allocation/pricing for the profit maximization problem on the highway.*

Proof. Recall that C is an upper bound on the edge capacities. Consider path $\mathcal{P}$ from s to t in D . The winner set is the union of all winning agents of nodes of $\mathcal{P}$. By the construction of D its nodes on level e can't accommodate more than c_e and agent i can't get item e that does not belong to

S_i . By condition 1 of the arcs definition an agent can be allocated with her entire bundle or with an empty bundle. By definition of the nodes set (condition 1) all allocations with higher price than agent's valuation are removed. By condition 2 of the node set no agent can envy other agents in $\mathcal{P}$.

We showed that $\mathcal{P}$ is giving a legal allocation/pricing that is *winner multi envy free*. Since the total weight of $\mathcal{P}$ gives the revenue (each winning agent price is summed once, when it first appears) we get that the heaviest path $\mathcal{P}$ yields an optimal solution.

The size of D is Each edge in the original graph translated to layer of nodes in D . For a layer there are at most m^C possible subsets of size $\leq \max\{c_e, |J^e|\}$ which is multiplied by the size of $\bigcup_k U_k^e$ which is bounded by B^{C^2} . Therefore there are at most $m^C B^{C^2}$ nodes in a layer. Each node in a layer has at most $n^C B^{C^2}$ edges to nodes in the next layer, this gives total of $m^{2C} B^{2C^2}$ arcs between two consecutive layers. This means that there are at most $m^{2C} B^{2C^2} n$ arcs in D . The computation time to find the longest path in D is linear in the number of arcs, since D is acyclic [1].

We continue with the proof of Theorem 20. By Lemma 21 we can build a winner multi envy free optimal solution to the problem in time $O(m^{2C} B^{2C^2} n)$. Then if we use simple algorithm (similar to Algorithm 1) that computes the smallest valuation collection of winners for each envious losing agent, from Lemma 19 we get an $O(m^{2C} B^{2C^2} n)$ algorithm as required.

8.3 FPTAS for Highway Revenue, $O(1)$ Edge Capacities, Multi Envy Freeness

We next show how to turn the dynamic programming algorithm into a fully polynomial time approximation scheme (FPTAS); that is, for any $\epsilon > 0$, we have an algorithm that computes a solution with profit at least $(1 - \epsilon)$ times the optimum profit, in time polynomial in the input and $\frac{1}{\epsilon}$. To that end, we just apply the dynamic programming algorithm on a rounded instance in which the agents' valuations are $b'_j = \lfloor b_j/K \rfloor$ where $K := (\epsilon B/m(n+1))$ for $\epsilon > 0$.

We show an FPTAS for the problem of finding an optimal winner multi envy free solution. By Lemma 19 we also get an FPTAS for the multi envy free problem as well.

Let us denote by (W, p) an allocation of winners (W) and prices for bundles (p). Let $\Pi(W, p)$ denote the revenue of the instance (W, p) .

Lemma 22 *For any winner multi envy free solution of the original (W, p) instance, there is a winner multi envy free solution (W, p') of the rounded instance so that $\prod(W, p) > \frac{1}{K} \prod(W, p') - mn - m$*

Proof. Let (W, p) be a feasible solution to the original instance with profit $\prod(W, p)$. At first for each bundle we set its price in the rounded instance as $p'_i = \lfloor p_i/K \rfloor$. Now we have a pricing that might be illegal, hence our second phase is to set each illegally priced bundle i (when agent i is envy) to be with price $\sum p'_j$ of the cheapest collection of bundles that cover S_i . During the first phase each bundle price is reduced by at most 1.

During the second phase each bundle price is reduced by at most n (number of items) as the size of the cheapest collection of bundles that cover S_i is bounded by n . The solution (W, p') is feasible to the rounded instance and:

$$\prod(W, p') = \sum_{j \in W} p'_j > \sum_{j \in W} (\frac{p_j}{K} - n - 1) \geq \frac{1}{K} \prod(W, p) - mn - m$$

Lemma 23 *For any winner multi envy free solution of the rounded (W', p') instance, there is a winner multi envy free solution $(W', \tilde{p})$ of the original instance so that $\prod(W', \tilde{p}) = K \prod(W', p')$.*

Proof. By multiplying the prices of the rounded instance by K we get prices that are still lower than the valuations (of the original instance), therefore this gives a valid solution for the original instance as required.

Now we combine the two lemmas to produce an FPTAS.

Theorem 24 *There exists an FPTAS for revenue maximization winner multi envy free highway problem with constant edge capacities.*

Proof. Let (W, p) be the optimal solution for the original instance. By rounding the valuations $b'_j = \lfloor b_j/K \rfloor$ we can compute optimal solution to the rounded instance (W', p') . By the process described in Lemma 23 we construct solution $(W', \tilde{p})$. By two previous lemmas this solution approximation to the optimal solution is

$$\begin{aligned} \prod(W', \tilde{p}) &= K \prod(W', p') \\ &> K(\frac{1}{K} \prod(W, p') - mn - m) \\ &= \prod(W, p') - \epsilon B \frac{m(n+1)}{m(n+1)} \end{aligned}$$

$$\text{Ergo, } \prod(W', \tilde{p}) \geq (1 - \epsilon) \prod(W, p).$$

Since Lemma 19 shows a polynomial algorithm that transform a winner multi envy free solution in the highway to a multi envy free solution, we get the following corollary:

Theorem 25 *There exist an FPTAS for the revenue maximization multi envy free highway problem with constant edge capacities.*

8.4 $O(1)$ Edge Capacities on Envy Free Subset Pricing on Highway

The problem can be solved in polynomial time by building an acyclic graph similar to the one in previous section but simpler. The number of possible prices is equal to the number of valuations (rather than B for multi envy free problem) as each price equals to some request valuation. In each level there are nodes for each valid subset of allocated agents accommodated by the segment and valid pricing assignment for these agents. The restriction on the graph is that two requests sharing a segment must not envy each other. By finding longest path on the polynomial size DAG the problem can be solved in polynomial time.

To summarize:

Theorem 26 *There exist polynomial time algorithm for the revenue maximization envy free highway problem with constant edge capacities.*

Fig. 4. Step by step example of turning pricing problem into the graph H . In the bundle requests, each agent would like to buy a set of products (the black balls) as long as its price is less than her valuation (the numbers in the bundle requests are valuations). A can be seen as a dependency graph where there is a vertical edge from each request i up to the requests of $A(i)$ (note there is no edge between 2 and 7 since $2 \leq 7$). At the last step the dependency graph is translated into the graph H as defined.

Fig. 5. Translating pricing assignment into graph G and finding path that covers the interval $[A, B]$ on a price lower than q . If such path exists, the request for interval $[A, B]$ is envious.

Fig. 6. Construction of multi envy free revenue maximization problem from *PARTITION*

Algorithm 2 Finding winner multi envy free pricing given an instance of the limited edge capacities highway problem

- (construction of digraph D) For each edge $e \in E$, we introduce a layer of nodes: Denote by J^e the set of agents j with $e \in S_j$. Let U_k^e holds all possible (sorted arbitrarily) subsets of J^e of size $k \leq \max\{c_e, |J^e|\}$. Define $\mathcal{H} = \{0, 1, \dots, B\}$ where B is the maximal valuation over all agents. Let H_k be the set of all square matrices over $\mathcal{H}$ of size $\leq k$. A pair $(U, H) \in U_k^e \times H_k$ represents having all agents in U as the only winning agents of e . The price agent $i \in U$ pays for S_i is h_{ii} and the value of the shortest possible path that pass through $j \in U$, start at the first arc of S_i and ends at e is h_{ij} . The set of all **nodes** in D is $\bigcup_{e \in E} \bigcup_{k \leq \max\{c_e, |J^e|\}} U_k^e \times H_k$ after we remove:

1. Illegal pricing nodes that have $h_{ii} > v_i$
2. Nodes that correspond to the last item of S_i for some agent i and $\exists j \in J^e : h_{ii} > h_{ij}$ (this means that i is envy of a group of agents including j that paid less for i 's bundle.

Draw an **arc** from node $(U, H) \in U_k^e \times H_k$ to $(U', H') \in U_{k'}^{e+1} \times H_{k'}$ for layers $2, \dots, n$ if the following conditions hold: (As U and U' are sorted, for simplicity, we denote a request as $j \in U$ and $j' \in U'$. When saying that $j' \notin U'$ the meaning is that all elements of U' does not relate to the same agent as $j \in U$.)

1. If agent $j \in U$ and $e+1 \in S_j$ then j appears also in U' . If $e \in S_j$ and $j \notin U$ then $j' \notin U'$
2. For agent $j \in U$ that also appears as $j' \in U'$ the pricing is consistent, formally:
 $h_{jj} = h'_{j'j'}$
3. For pair of agents $i, j \in U$ that both appear also in U' as i', j' respectively, the shortest path from beginning of i through j stays consistent, formally:
 $h_{ij} = h'_{i'j'}$
4. For agent $j' \in U' \setminus U$ (meaning its correspondent j does not appear in U) and for each $i' \in U'$, $h'_{i'j'}$ should be equal to $h'_{j'j'} + \min_d h_{id}$ (if $i \notin U$ then the min expression is set to zero) - this gives the shortest path computation through each added agent to the allocation

We connect node s to all nodes in layer 1 and we connect all nodes in layer $n+1$ to t . For each arch that goes from node $(U, H) \in U_k^e \times H_k$ into node $(U', H') \in U_{k'}^{e+1} \times H_{k'}$ we give weight of $\sum_{j' \in U' \setminus U} h'_{j'j'}$.

- Compute the longest $s \rightarrow t$ path $\mathcal{P}$ in digraph D . The winner set is the set of agents that appear in U component of some node of $\mathcal{P}$. The pricing of certain agent that appear as $j \in U$ of some node of $\mathcal{P}$ is h_{jj} of the same node.
-
